1.0 Executive Summary

Biological monitoring of streams and rivers is an integral component of the water quality monitoring program in the Commonwealth of Virginia. Biological monitoring allows the Virginia Department of Environmental Quality (VDEQ) to assess the ecological condition of streams and rivers. Biological surveys are used to answer the question of whether these waterbodies support survival and reproduction of desirable aquatic species and determine if the waterbodies meet their designated aquatic life uses.

In 2000, the United States Environmental Protection Agency (USEPA) contracted TetraTech to develop a multimetric macroinvertebrate index for the Commonwealth of Virginia. This index contains eight core metrics that when calculated into one number is known as the Virginia Stream Condition Index (VSCI) (TetraTech, 2003). TetraTech developed the VSCI using Virginia's existing biomonitoring database, which contained a significant amount of upstream (reference) control sites for use with the Rapid Bioassessment Protocols (USEPA, 1999). Reference sites in the central Appalachian ecoregion, piedmont ecoregions and headwater streams were limited.

Using an independent, new probabilistic database (sample n=350) with data collected from 2001-2004, Virginia has validated the VSCI using a spatially diverse (ecoregionally and stream size) data set free of psuedoreplication. These probabilistic data sets have allowed Virginia Department of Environmental Quality (VDEQ) to narrow data gaps and test the proposed VSCI against many classification variables, which include season, stream size, ecoregion, bioregion, river basin, regional office, and sampling technique. VDEQ also reviewed the recommended best standard values for the eight core metrics. These metrics include EPT taxa, total taxa, % Ephemeroptera, % Plecoptera plus Trichoptera less Hydropsychidae, % Chironomidae, % Top 2 Dominant Taxa, Modified Family Biotic Index (MFBI), and % Scrapers. This report focuses on validating the VSCI and proposing assessment recommendations. For a detailed explanation of multimetric index development, metric definitions, and an overview of bioassessment, please review the document 'A Stream Condition Index for Virginia Non-Coastal Streams' at http://www.deq.virginia.gov/watermonitoring/pdf/vastrmcon.pdf.

Reviewing the probabilistic biological data has confirmed that the VSCI works well to discriminate between sites with acceptable water quality and habitat versus sites with degraded water quality and habitat. Potential seasonal, ecoregion, bioregion, basin size, and sampling method patterns were found in NMS ordinations results. However, MeanSim statistical results indicated that these patterns have low classification strength. These patterns were further tested for environmental significance using PCA to evaluate metric clustering by classification category. The PCA failed to display any clustering of metrics by classification. Box-and-whisker plots of the metrics and the VSCI were used to graphically determine any impacts of these classifications on the reference stations. Individual metric differences were noted by classification category. However, differences in individual core metrics did not affect the overall VSCI score. The median values for the VSCI in the box-and-whisker plots were similar and the

interquartile ranges of the VSCI scores in all of the graphs were above 60. Current data analysis results do not support calibrating the VSCI by season, sampling method, bioregion, or basin size. Recommending new best standard values for calculating the VSCI is not necessary. Results of calibrating the best standard values by bioregion and/or season are predictable. Mountain streams VSCI scores are slightly depressed and piedmonts VSCI scores are slightly higher. The same overall percentage of streams would be designated impacted streams because the calibrated reference sites adjust in the same manner thereby lowering or raising the assessment cutoff.

Aquatic Life Use (ALU) tiers established using the Virginia SCI

The 10th percentile from the probabilistic data set was 58.5 and the 10th percentile from Tetratech's analysis of targeted data was 61.3. The average 10th percentile cutoff from both data sets is 59.9. To keep the assessment cutoff simple, the assessment threshold was rounded to 60. Using the entire non-coastal population a CDF curve was generated for the VSCI (Figure 20). The current data set shows that at a VSCI score of 60 the lower 95th percent confidence interval is 55 and the upper 95th percent confidence interval is 63. This confidence interval range of 55 to 63 establishes a "gray zone" which incorporates the known variability in the non-coastal populations. When the VSCI score is above 63, VDEQ is more confident that the stream is approaching reference condition and below 55 VDEQ is more confident that the stream is impacted from some type of stress. The precision of the VSCI was estimated to be +/- 7.9 scoring units on a 100 point scale.

Aquatic life use tiers were established above and below the gray zone (Table E-1) based on the average 50th percentile scores from the Tetra Tech reference dataset and the ProbMon reference dataset (upper tier); and the Tetra Tech stressed dataset and ProbMon stressed dataset (lower tier). Assessment determination and methodology based on the VSCI aquatic life use tiers will be found in DEQ's 2008 Water Quality Assessment Guidance Manual

Table E-1. Virginia SCI scores and associated aquatic life use (ALU) tiers.

VSCI Score	ALU tiers
<42	Severe Stress
42-55	Moderate Stress
55-63	Unknown/Fair (Gray Zone)
63-73	Good
>73	Excellent

2.0 Introduction

In 2000, the United States Environmental Protection Agency (USEPA) contracted TetraTech to develop a multimetric macroinvertebrate index for the Commonwealth of Virginia. This index contains eight core metrics that are collectively known as the Virginia Stream Condition Index (VSCI) (TetraTech, 2003). TetraTech developed the VSCI using Virginia's existing biomonitoring database, which contained a significant amount upstream control sites for use with the Rapid Bioassessment Protocols (USEPA, 1999). Reference sites in the central Appalachian ecoregion, piedmont ecoregions and headwater streams were limited.

Using an independent, new probabilistic database (sample n=350) with data collected from 2001-2004, Virginia has validated the VSCI using a spatially diverse (ecoregionally and stream size) data set free of psuedoreplication. Virginia also used data from West Virginia's probabilistic program that met the reference filter criteria to evaluate additional reference sites located in the central Appalachian ecoregion. These probabilistic data sets have allowed Virginia Department of Environmental Quality (VDEQ) to narrow data gaps and to test the proposed VSCI by season, stream size, ecoregion, bioregion, river basin, regional office, and sampling technique. VDEQ also reviewed the recommended best standard values for the eight core metrics. These metrics include EPT taxa, total taxa, % Ephemoeroptera, % Plecoptera plus Trichoptera less Hydropsychidae, % Chironomidae, % Top 2 Dominant Taxa, Modified Family Biotic Index (MFBI), and % Scrapers. This report focuses on validating the VSCI and proposing assessment recommendations. For a detailed explanation of multimetric index development, metric definitions, and an overview of bioassessment, please review the document 'A Stream Condition Index for Virginia Non-Coastal Streams' at

http://www.deq.virginia.gov/watermonitoring/pdf/vastrmcon.pdf.

Reference and stress filters (Table 1-3) were developed to screen large amounts of data and to define the least disturbed condition and stressed conditions found in Virginia streams. The reference and stress filters use data from land cover, water quality, and habitat. The values used to screen for reference condition were from a variety of sources including the literature (Miltner 1998, USEPA 2000, Dodd 2000, Ohio EPA 1999, Boward 1999, Carle 2005, Wang 2003) and VDEQ data analysis (TetraTech 2003 and VDEQ 2005). Best Professional Judgment (BPJ) was used to eliminate candidate sites that agency biologists knew were not reference or stress condition from their site specific watershed knowledge.

Table 1. List of piedmont ecoregion reference filters (n=10).

Piedmont Reference Filter	
% Urban	< 5%
Total Nitrogen	< 1.5 mg/L
Total Phosphorus	< 0.05 mg/L

Specific Conductance (uS/cm)	< 250
Dissolved Oxygen	> 6 mg/L
рН	> 6 or < 9
Channel Alteration	> 11
Epifaunal Substrate/Cover	> 11
Embeddedness	> 11
Riparian Vegetative Zone	> 11
Total Habitat	> 140

Table 3. List of stress filters all ecoregions (n=6).

Stress Filter	
% Urban	> 10%
Total Nitrogen	> 3 mg/L
Total Phosphorus	> 0.1 mg/L
Specific Conductance (uS/cm)	> 500
Riparian Vegetative Zone	< 6
Total Habitat	< 120

VDEQ identified 60 (sample n=104) new reference sites and 33 (sample n=64) stressed sites from the probabilistic data sets for this validation study. The breakdown of the reference and stressed sites by season and ecoregion is found in Tables 5 and 6. A map of the stations by ecoregion is found in Figure 1.

3.0 Methods

The data used in this study were collected according to VDEQ standard operating procedures set forth by the ambient monitoring program

http://www.deq.virginia.gov/watermonitoring/pdf/wqmsop.pdf and probabilistic monitoring program http://www.deq.virginia.gov/probmon/pdf/report1.pdf.

Probabilistic data is stored in a Microsoft Access database. The land cover, nutrient, and field data tables were queried using the reference and stress filters described in the introduction. Stations categorized by reference and stress query conditions were reviewed by regional biologists. The final data sets of reference and stress stations were compiled in new Microsoft Access tables for use in PC-ORD Version 4 (McCune 1999), MeanSim (Van Sickle 1997), SYSTAT11, SAS, R, and ArcView 3.2.

The reference taxa data were graphically reviewed using Nonmetric Multidiemnsional Scaling (NMS) ordination and statistically explored for differences using the MeanSim program. Significant classification differences would result in recommending recalibration of the VSCI for assessment purposes. These classification differences were tested for environmental significance using Principle Components Analysis (PCA) and box-and-whisker plots. Best Standard Values (BSV) from the targeted Ecological Data Application System (EDAS) database and the probabilistic database were compared. Reference and stress box-and-whisker plots were generated to recommend an assessment value and to assess the accuracy of the VSCI (the percent of correctly assessed stations). Precision of the VSCI was tested using replicate stations. Cumulative distribution functions were generated for the entire non-coastal area of Virginia to understand the variability in the population associated with the core metrics and VSCI.

Using PC-ORD, Nonmetric Multidiemnsional Scaling (NMS) was used to graphically evaluate patterns in the reference community data by bioregion, ecoregion, season, stream order, basin size, VDEQ regional office (including West Virginia data), collection method, and river basin. Two bioregions were defined in Virginia, one bioregion is all of the mountain ecoregions (Blue Ridge Mountain, Central Appalachian Ridge and Valley, and Central Appalachian) and the other bioregion is all of the piedmont ecoregions (Piedmont and Northern Piedmont). NMS ordinations were used to graphically explore the reference community data to find patterns. The NMS graphs presented in this report were generated by Log (X+1) transforming the reference taxa. Rare taxa were not excluded from the analysis.

Graphical patterns were further explored using the MeanSim analysis program. MeanSim software and documentation is provided free of charge on EPA's website http://www.epa.gov/naaujydh/pages/models/dendro/meansim6.htm. MeanSim analysis is based on a matrix of pairwise similarities for all possible pairs of objects (Van Sickle 1997). VDEQ used a Bray-Curtis similarity input matrix for all MeanSim analysis. MeanSim analysis was performed by bioregion, ecoregion, season, stream order, basin size, and collection method. The program outputs Within Group (W) similarity and Between Group (B) similarity. Classification

strength (CS) can be estimated by subtracting B from W (CS=W-B). M is calculated by dividing B by W (M=B/W), if the 'no class structure' hypothesis is true, then M should yield a value close to 1. The MeanSim program outputs a p-value based on 10,000 permutations of the input matrix. Information provided from MeanSim is used to evaluate the strength of classification categories. It is important to determine the environmental significance of MeanSim results.

Environmental significance was tested using Principle Components Analysis (PCA) and box-and-whisker plots. Using the eight core metrics from reference stations PCA plots were produced in PC-ORD and evaluated by season, bioregion, ecoregion, basin size, and collection method. The richness metrics were log transformed and the proportion metrics were arcsin transformed in the input matrix. The PCA graphs were evaluated to identify clusters of metrics by classification categories. Box-and-whisker plots of the eight core metrics and the VSCI from reference stations were graphically evaluated by season, bioregion, basin size, and collection method to determine if these classifications impacted individual core metric values and final VSCI scores.

Cumulative distribution function (CDF) plots were generated using the R program. The CDF estimates the probability that a variable is less than or equal to some value. This function is most useful when displayed graphically. The analyst is able to determine the likelihood that a variable would be less than a particular threshold. It can also provide the probability that a variable would be above a threshold or if it would be within a certain range. For probabilistic data used in this validation, these probabilities apply to non-tidal streams found in the mountain and piedmont ecoregions. Detailed information on CDF curve generation can be found at the following EPA website: http://www.epa.gov/nheerl/arm/analysispages/monitanalysisinfo.htm.

CDF plots were created from the probabilistic data set to generate best standard values for each recommended core metric value and the VSCI. These probabilistic best standard values were compared to the recommended best standard values from TetraTech's report, which used targeted stations found in EDAS.

Box-and-whisker plots for reference and stressed sites and their corresponding percentile values were generated using the SYSTAT11 program. Percentiles were used to determine assessment values for this data set. VSCI accuracy (the percent of correctly assessed stations) was determined using this information. VSCI precision was calculated using replicate stations. Precision was calculated by calculating the root mean square error (RMSE), which estimates sampling error associated with a method. The VSCI precision was estimated by determining the 90% confidence interval (1.645 X RSME) (Maxted 2000). The last measure of variability was the signal-to-noise ratio (S/N) which estimated the variance among all sites to the replicate sites (Kauffman 1999). Larger S/N ratio indicates lower relative variability. The S/N ratio was calculated in SAS. Maps were produced using ArcView 3.2.

4.0 Data Results

NMS and MeanSim results are presented first, followed by PCA and box-and-whisker plots which evaluate environmental significance of select classification categories. Next best standard value assessment results from CDF curves for the core metrics and the VSCI are shown. Finally, box-and-whisker plots with corresponding reference site percentiles are presented.

4.1 NMS ordination results

NMS graphs were produced by running PC-ORD NMS 'slow and thorough setting' on Autopilot Mode with a Log (X+1) transformation to produce the following tables and graphs. The final stress was 17.49 and accounted for 80.6% of the variation.

Table 6. Stress in relation to dimensionality (number of axes)

Stress in real data 40 run(s)					ress in r nte Carlo		data 50 runs
Axes	Minimum	Mean	Maximum	Minimum	Mean	Maximum	p
1 2 3 4 5 6	37.530 22.982 17.493 14.247 11.981 10.235	44.893 23.868 17.935 14.341 12.061 10.334	57.177 41.250 18.413 14.886 12.511 10.783	49.390 31.892 23.715 18.938 15.661 13.297	52.635 32.835 24.461 19.598 16.295 13.854	57.175 34.425 25.676 20.492 16.851 14.328	0.0196 0.0196 0.0196 0.0196 0.0196

p = proportion of randomized runs with stress < or = observed stress

Table 7. Variation explained by axis (r squared)

Axis	Increment	Cumulative	
1	.391	.391	
2	.143	.533	
3	.273	.806	

Figures 2-9 contain the NMS ordination results. Only graphs of axis 1 and 3 are presented in this report since axis 1 and 3 explain the greatest amount of variation. The points on each of these graphs represent individual reference sites.

Season (Figure 2), ecoregion (Figure 3), bioregion (Figure 4), bioregion and season (Figure 5), basin size (Figure 6), and sampling method (Figure 8) contain potential clustering of reference sites and were further evaluated for statistical (Table 8) and environmental significance (Figure 10-19). The VDEQ regional office (Figure 7) and river basin (Figure 9) ordinations do not contain any potential patterns.

Figure 2. NMS (n=104) results by season.

The open red triangles represent reference stations sampled in the fall season and the solid green diamonds represent reference stations sampled in the spring season.

Figure 3. NMS (n=104) results by ecoregion.

The open red triangles represent reference stations sampled in ecoregion 45 (piedmont), the solid green diamonds represent reference stations sampled in ecoregion 64 (northern piedmont), the blue asterisk represent reference stations sampled in ecoregion 66 (blue ridge mountains), the upside down solid pink triangles represent reference stations sampled in ecoregion 67 (central appalachian ridge and valley), and the open blue diamonds represent stations sampled in ecoregion 69 (central appalachian).

Figure 4. NMS (n=104) results by bioregion.

The open red triangles represent reference stations sampled in the mountain bioregion (blue ridge mountains, central appalachian, and central appalachian ridge and valley ecoregions) and the solid green diamonds represent reference stations sampled in the piedmont bioregion (piedmont and northern piedmont ecoregions).

Figure 5. NMS (n=104) results by bioregion and season.

The open red triangles represent reference stations sampled during the fall season in the mountain bioregion, the solid green diamonds represent reference stations sampled during the fall season in the piedmont bioregion, the blue asterisk represent reference stations sampled during the spring season in the mountain bioregion, and the solid upside down triangles represent reference stations sampled during the spring season in the piedmont bioregion.

Figure 6. NMS (n=104) results by basin size.

The open red triangles represent reference stations with a watershed size less than 1 square mile, the solid green diamonds represent reference stations with a watershed size between 1 square mile and 10 square miles, the blue asterisk represent reference stations with a watershed size between 10 square miles and 200 square miles, and the solid upside down triangles represent reference stations with a watershed size greater than 200 square miles.

Figure 7. NMS (n=104) results by regional office (including West Virginia data).

The open red triangles represent reference stations sampled in VDEQ's Northern Region Office (NRO), the solid green diamonds represent reference stations sampled in VDEQ's Piedmont Region Office (PRO), the blue asterisk represent reference stations sampled in VDEQ's South Central Region Office (SCRO), the upside down solid pink triangles represent reference stations sampled in VDEQ's Southwest Region Office (SWRO), the open blue diamonds represent stations sampled in VDEQ's Valley Region Office (VRO), the solid yellow squares represent stations sampled in VDEQ's West Central Region Office (WCRO), and the open red circles represent stations sampled in West Virginia's probabilistic sampling that met VDEQ reference filters.

Figure 8. NMS (n=104) results by sampling method.

The open red triangles represent reference stations sampled using VDEQ's multi-habitat method, the solid green diamonds represent reference stations sampled using VDEQ's riffle method, and the blue asterisk represent reference stations sampled using West Virginia's riffle method.

Figure 9. NMS (n=104) results by river basin.

The open red triangles represent reference stations sampled in the Potomac and Shenandoah river basins, the solid green diamonds represent reference stations sampled in the James river basin, the blue asterisk represent reference stations sampled in the Rappahannock river basin, the upside down solid pink triangles represent reference stations sampled in the Roanoke river basin, the open blue diamonds represent stations sampled in the Chowan river basin, the solid yellow squares represent stations sampled in the Holston, Big Sandy, and Tennessee river basins, the open red circles represent stations sampled in the New river basin, and the solid brown circles represent stations sampled in West Virginia (includes the Cheat, New, Greenbrier, Coal, and Elk river basins).

4.2 MeanSim results

Season (Figure 2), ecoregion (Figure 3), bioregion (Figure 4), basin size (Figure 6), and sampling method (Figure 8) contain potential clustering of reference sites and were further evaluated statistically using MeanSim (Table 8).

The classification strength of these classification categories was low. Thus overall within group similarity was not different from between group similarity. Combining potential classification categories such as season and bioregion did not improve the classification strength. MeanSim results do not warrant recalibrating the VSCI for use in different seasons, ecoregions, or basin sizes. However, these classifications were tested for environmental significance (Figure 10-19).

Percent similarity can be graphically evaluated using a mean similarity dendrogram (Van Sickle 1997). Appendix A contains mean similarity dendrogram graphs for all of the categories in Table 8.

Table 8. MeanSim analysis results

Bray Curtis Similarity Matrix							
	N (ref sites)	N (Groups)	Within Group (W)	Between Group (B)	CS (W-B)	M (B/W)	p-value
Season	104	2	35.9%	31.7%	4.3%	0.88	0.0001
Basin Size	104	4	35.1%	32.7%	2.3%	0.93	0.0002
Ecoregion (III)	104	5	36.4%	32.9%	3.5%	0.91	0.0001
Bioregion	104	2	34.5%	32.2%	2.3%	0.93	0.0001
Bioregion and Season	104	4	36.8%	32.4%	4.4%	0.88	0.0001
Collection Method	104	3	35.1%	32.6%	2.5%	0.93	0.0033

4.3 Environmental significance results

Potential seasonal, ecoregion, bioregion, basin size, and sampling method patterns were found in NMS ordinations results. MeanSim statistical results indicated that these patterns have low classification strength. In order to determine if these classification categories impact the core biological metrics in an environmentally significant fashion, PCA was run to evaluate metric clustering by classification category. Box-and-whisker plots of the metrics and the VSCI were used to graphically determine any significant variation on the reference stations by classification category.

The PCA results (Figures 10-15) were generated using a variance-covariance matrix centered by parameters. Axis 1 and 2 accounted for approximately 95.7% of the variation. The metric vectors represent Pearson correlations of a least 0.02 with Axis 1 or 2. None of the stations form distinct patterns in Figures 10-15 and the metric vectors do not cluster in any one direction, but are spread out in the graphs.

Metric and VSCI box-and-whisker plots (Figures 16-19) were generated by season, bioregion, basin size, and sampling method. Individual metrics were different by classification category. Season (Figure 16) had little difference in individual metrics and the VSCI except for % scrapers, which were higher in the fall and % chironomidae, which were higher in the spring. In the graphs for bioregion (Figure 17) and sampling method (Figure 19), the EPT taxa and MFBI metrics were different. The EPT taxa were higher in the mountain bioregion compared to the piedmont bioregion. EPT numbers were higher in reference sites sampled with the riffle method versus the sites sampled with the multi-habitat method. References stations with a watershed less than 1 square mile (Figure 18) have a higher percentage % Plecoptera plus Trichoptera less Hydropsychidae. However, the differences in individual core metrics do not appear to affect the final VSCI score. The median values for the VSCI in the graphs were similar and the interquartile ranges of the VSCI scores in all of the box-and-whisker plots were above 60.

Figure 10. PCA(n=104) metric results by season.

The open red triangles represent reference stations sampled in the fall season and the solid green diamonds represent reference stations sampled in the spring season.

Figure 11. PCA (n=104) metric results by bioregion.

The open red triangles represent reference stations sampled in the mountain bioregion (blue ridge mountains, central appalachian, and central appalachian ridge and valley ecoregions) and the solid green diamonds represent reference stations sampled in the piedmont bioregion (piedmont and northern piedmont ecoregions).

Figure 12. PCA (n=104) metric results by bioregion and season.

The open red triangles represent reference stations sampled during the fall season in the mountain bioregion, the solid green diamonds represent reference stations sampled during the fall season in the piedmont bioregion, the blue asterisk represent reference stations sampled during the spring season in the mountain bioregion, and the solid upside down triangles represent reference stations sampled during the spring season in the piedmont bioregion.

Figure 13. PCA (n=104) metric results by ecoregion.

The open red triangles represent reference stations sampled in ecoregion 45 (piedmont), the solid green diamonds represent reference stations sampled in ecoregion 64 (northern piedmont), the blue asterisk represent reference stations sampled in ecoregion 66 (blue ridge mountains), the upside down solid pink triangles represent reference stations sampled in ecoregion 67 (central appalachian ridge and valley), and the open blue diamonds represent stations sampled in ecoregion 69 (central appalachian).

Figure 14. PCA (n=104) metric results by basin size.

The open red triangles represent reference stations with a watershed size less than 1 square mile, the solid green diamonds represent reference stations with a watershed size between 1 square mile and 10 square miles, the blue asterisk represent reference stations with a watershed size between 10 square miles and 200 square miles, and the solid upside down triangles represent reference stations with a watershed size greater than 200 square miles.

Figure 15. PCA (n=104) metric results by sampling method.

The open red triangles represent reference stations sampled using VDEQ's multi-habitat method, the solid green diamonds represent reference stations sampled using VDEQ's riffle method, and the blue asterisk represent reference stations sampled using West Virginia's riffle method.

Figure 16. Box-and-whisker plot of core metrics and VSCI by season.

The spring sampling season (n=56) occurs from March to June and the fall sampling (n=48) occurs from August to November.

Fall Spring SEASON II Spring SEASON

II Spring SEASON

Figure 17. Box-and-whisker plot of core metrics and VSCI by bioregion.

The mountain bioregion (n=71) is made up of the blue ridge mountain, central appalachian, and central appalachian ridge and valley ecoregions. The piedmont bioregion (n=33) is made up of the northern piedmont and piedmont ecoregions.

Figure 18. Box-and-whisker plot of core metrics and VSCI by basin size.

Headwater streams (n=14) were defined as a watershed with less than 1 square mile, small streams (n=29) were defined as stations with a watershed size between 1 square mile and 10 square miles, reference stations with a watershed size between 10 square miles and 200 square miles were defined as large streams and small rivers (n=54), and reference stations with a watershed size greater than 200 square miles were defined as rivers (n=7). These delineations were based on descriptions by Ohio EPA (Ohio EPA 1999).

Figure 19. Box-and-whisker plot of core metrics and VSCI by sampling method.

The multi-habitat sampling method (n=10) is abbreviated using MACS and the riffle sample method (n=94) is abbreviated using RBP II in Figure 19.

4.4 Best standard value (BSV) analysis results

CDF curves of the eight core metrics were used to generate statewide best standard values (BSV). Please see Appendixes B-D for complete data output of the core metrics. Average BSV recommended by TetraTech along with the average probabilistic BSV are in Table 9. CDF BSV results by individual season and bioregion are in Table 10.

VSCI scores were calculated with bioregion and season specific BSV and average BSV to determine if there were any significant advantages in using the recalibrated BSV (Figures 23 to 26) method over the average best standard value method (Figures 20 to 22).

The probabilistic values were generated from an estimate of the entire population of these metrics in the non-coastal region of Virginia. In six out of eight core metrics, the estimated probabilistic confidence intervals overlapped with TetraTech's recommended best standard values. The confidence interval for % Plecoptera plus Trichoptera less Hydropsychidae was quite large from 39.7 to 80.3 (see Appendix B for detailed output). The estimate for % Ephemeroptera was different, but less than 10 points from the highest confidence limit.

Figure 25. Spring piedmont BSV comparison VSCI CDF and percentiles

Figure 26. Fall piedmont BSV comparison VSCI CDF and percentiles

Using ecoregionally and seasonally calibrated BSV lowers overall Mountain scores in both seasons. The same calibration raises overall Piedmont scores in both seasons. This result is expected as average BSV tend to be slightly reduced for mountain streams and slightly for piedmont streams.

4.5 VSCI discrimination ability and reference percentiles.

The VSCI works well to discriminate between sites with acceptable water quality and habitat versus sites with degraded water quality and habitat. The 10th percentile from the probabilistic data set was 58.5, which is a few points lower than the 10th percentile of 61.3 reported by TetraTech from the targeted database.

Figure 27. Box-and-whiskers all reference (n=104) versus all stress (n=64)

4.6 VSCI variability

Virginia's probabilistic program replicated 5% (n=16) of the non-coastal sampling effort. Descriptive statistics, precision calculations, and signal-to-noise ratios from these replicate stations by season are found in Table 11. VSCI scores are relatively stable and the overall precision of the index is good (precision is calculated at the 90% confidence interval). A certain amount of variability is associated with biological indexes. This variation is due to natural variation in hydrology, water chemistry, and habitat throughout the commonwealth of Virginia. The VSCI appears to less variable in the fall than in the spring sampling season. The precision is better in the fall and the signal-to-noise ratio is much higher. However, many factors are affecting this randomly replicate data set and more data is necessary to confirm this trend. It appears much higher quality sites were replicated in the fall which may explain the lower variability associated with the fall sampling season in this data set.

Table 11. Descriptive statistics, precision, and signal-to-noise results from replicate samples.

Category	Mean (Field Samples)	Mean (Duplicate Samples)	S.D. (Field Samples)	S.D. (Duplicate Samples)	Precision	Signal-to-Noise
All Seasons	62.7	63.4	12.1	12.2	7.9	1.9
All Fall	70.7	71.9	4.9	6.0	4.7	24.6
All Spring	54.6	55.0	11.9	11.0	10.1	4.2

5.0 Conclusions and Recommendations

After reviewing the probabilistic biological data it has been confirmed that the VSCI works well to discriminate between sites with acceptable water quality and habitat versus sites with degraded water quality and habitat. Potential seasonal, ecoregion, bioregion, basin size, and sampling method patterns were found in NMS ordination results. However, MeanSim statistical results indicated that these patterns have low classification strength. These patterns were further tested for environmental significance using PCA to evaluate metric clustering by classification category. The PCA failed to display any clustering of metrics by classification. Box-and-whisker plots of the metrics and the VSCI were used to visually determine any classification influence on the reference stations. Individual metric differences were noted by classification category. Season showed little difference in individual metrics and the VSCI except for % Scrapers (higher in the fall) and % Chironomidae (higher in the spring). In plots classified by bioregion and sampling method it was noted that EPT taxa and MFBI metrics were different. The EPT taxa were higher at the mountain bioregion compared to the piedmont bioregion. EPT numbers were higher at reference sites sampled using the riffle method versus the sites sampled with the multihabitat method. References stations with a watershed less than 1 square mile have a higher percentage of Plecoptera plus Trichoptera less Hydropsychidae. However, differences in individual core metrics were balanced out by the VSCI. The median values for the VSCI in the box-and-whisker plots were similar and the interquartile ranges of the VSCI scores in all of the graphs were above 60.

Current data analysis results do not support calibrating the VSCI by season, sampling method, bioregion, or basin size. Additionally, recalibrating the VSCI by one of these classifications schemes would lower confidence in the assessment screening value by lowering the number of reference sites available in these categories. Recommending new best standard values for calculating the VSCI is not necessary as this point and will require addition data analysis. Results of calibrating the best standard values by bioregion and/or season are predictable. Mountain stream VSCI scores are slightly depressed and piedmont VSCI scores are slightly higher when calibrated by bioregion and/or season. The overall percentage of streams designated as impacted would not change because the calibrated reference sites adjust in the same manner thereby lowering or raising the assessment cutoff. % Plecoptera plus Trichoptera less Hydropsychidae best standard value will be further reviewed when confidence intervals from probabilistic data yield more precise estimates.

Aquatic Life Use (ALU) tiers established using the Virginia SCI

The 10th percentile from the probabilistic data set was 58.5 and the 10th percentile from Tetratech's analysis of targeted data was 61.3. The average 10th percentile cutoff from both data sets is 59.9. To keep the assessment cutoff simple, the assessment threshold was rounded to 60. Using the entire non-coastal population a CDF curve was generated for the VSCI (Figure 20). The current data set shows that at a VSCI score of 60 the lower 95th percent confidence interval is 55 and the upper 95th percent confidence interval is 63. This confidence interval range of 55 to

63 establishes a "gray zone" which incorporates the known variability in the non-coastal populations. When the VSCI score is above 63, VDEQ is more confidant that the stream is approaching reference condition and below 55 VDEQ is more confidant that the stream is impacted from some type of stress. The precision of the VSCI was estimated to be +/- 7.9 scoring units on a 100 point scale. This precision was calculated using data from replicate stations that were collected on the same day.

Aquatic life use tiers were established above and below the gray zone (Table 12) based on the average 50th percentile scores from the Tetra Tech reference dataset and the ProbMon reference dataset (upper tier); and the Tetra Tech stressed dataset and ProbMon stressed dataset (lower tier) (Table 13). The aquatic life use tiers that can be discerned using the Virginia SCI is shown in Figure 28. Assessment determination and methodology based on the VSCI aquatic life use tiers can be found in DEQ's 2008 Water Quality Assessment Guidance Manual

Table 12. Virginia SCI scores and associated aquatic life use (ALU) tiers

VSCI Score	ALU tiers
<42	Severe Stress
42-55	Moderate Stress
55-63	Unknown/Fair (Gray Zone)
63-73	Good
>73	Excellent
